Limitations of Global Value Numbering

As presented, our global value numbering technique doesn't recognize (or handle) computations of the same expression that produce different values along different paths.

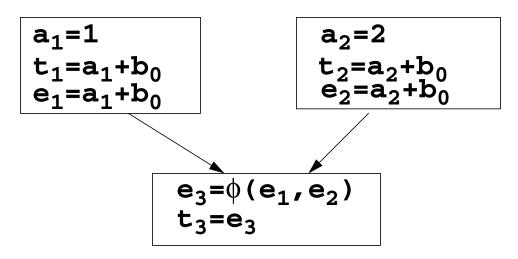

Thus in

variable a_3 isn't equivalent to either a_1 or a_2 .

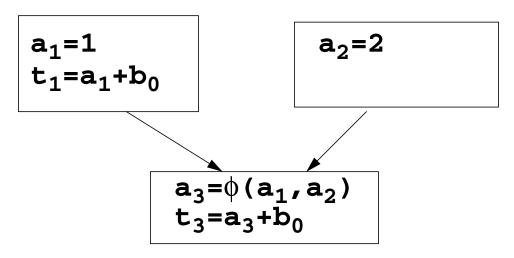

But,

we can still remove a redundant computation of a+b by moving the computation of t_3 to each of its predecessors:

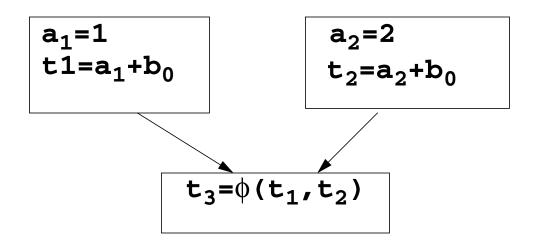

Now a redundant computation of a+b is evident in each predecessor block. Note too that this has a nice register targeting effect— e_1 , e_2 and e_3 can be readily mapped to the same live range.

The notion of moving expression computations above phi functions also meshes nicely with notion of partial redundancy elimination. Given

moving a+b above the phi produces

Now a+b is computed only once on each path, an improvement.

Partial Redundancy Analysis

Partial Redundancy Analysis is a boolean-valued data flow analysis that generalizes available expression analysis.

Ordinary available expression analysis tells us if an expression must already have been evaluated (and not killed) along *all* execution paths.

Partial redundancy analysis, originally developed by Morel & Renvoise, determines if an expression has been computed along *some* paths. Moreover, it tells us where to add new computations of the expression to change a partial redundancy into a full redundancy.

This technique *never* adds computations to paths where the computation isn't needed. It strives to avoid having any redundant computation on any path.

In fact, this approach includes movement of a loop invariant expression into a preheader. This loop invariant code movement is just a special case of partial redundancy elimination.

Basic Definition & Notation

For a Basic Block i and a particular expression, e:

Transp_i is true if and only if e's operands aren't assigned to in i.

 $Transp_i \equiv \neg Kill_i$

Comp_i is true if and only if e is computed in block i and is not killed in the block after computation.

 $Comp_i \equiv Gen_i$

AntLoc_i (Anticipated Locally in i) is true if and only if e is computed in i and there are no assignments to e's operands prior to e's computation. If AntLoc_i is true, computation of e in block i will be redundant if e is available on entrance to i.

We'll need some standard data flow analyses we've seen before:

AvIn_i = Available In for block i = 0 (false) for b_0

= AND AvOut_p
p ∈ Pred(i)

 $AvOut_i = Comp_i OR$ $(AvIn_i AND Transp_i)$ $\equiv Gen_i OR$ $(AvIn_i AND - KiII_i)$

We anticipate an expression if it is very busy:

AntOut_i = VeryBusyOut_i

= 0 (false) if i is an exit block

= AND AntIn_s
s ∈ Succ(i)

 $AntIn_i = VeryBusyIn_i$

= AntLoc_i OR (Transp_i AND AntOut_i)

Partial Availability

Partial availability is similar to available expression analysis except that an expression must be computed (and not killed) along *some* (not necessarily *all*) paths:

PavIn_i

= 0 (false) for b_0

= OR PavOut_p
p ∈ Pred(i)

 $PavOut_i = Comp_i OR$ $(PavIn_i AND Transp_i)$

Where are Computations Added?

The key to partial redundancy elimination is deciding where to add computations of an expression to change partial redundancies into full redundancies (which may then be optimized away).

We'll start with an "enabling term."

 $Const_i = AntIn_i AND$ $[PavIn_i OR (Transp_i AND - AntLoc_i)]$

This term say that we require the expression to be:

- (1) Anticipated at the start of block i (somebody wants the expression) and
- (2a) The expression must be partially available (to perhaps transform into full availability)

or

(2b) The block neither kills nor computes the expression.

Next, we compute PPIn_i and PPOut_i. PP means "possible placement" of a computation at the start (PPIn_i) or end (PPOut_i) of a block.

These values determine whether a computation of the expression would be "useful" at the start or end of a basic block.

PPOut_i

- = 0 (false) for all exit blocks
- $= AND PPIn_{S}$ $s \in Succ(i)$

We try to move computations "up" (nearer the start block).

It makes sense to compute an expression at the end of a block if it makes sense to compute at the start of all the block's successors.

```
PPIn_i = 0 (false) for b_0.

= Const_i
AND (AntLoc<sub>i</sub> OR (Transp<sub>i</sub> AND PPOut<sub>i</sub>))

AND (PPOut<sub>p</sub> OR AvOut<sub>p</sub>)
p \in Pred(i)
```

To determine if PPIn_i is true, we first check the enabling term. It makes sense to consider a computation of the expression at the start of block i if the expression is anticipated (wanted) and partially available or if the expression is anticipated (wanted) and it is neither computed nor killed in the block.

We then check that the expression is anticipated locally or that it is unchanged within the block and possibly positioned at the end of the block.

CS 701 Fall 2006

Finally, we check that all the block's predecessors either have the expression available at their ends or are willing to position a computation at their end.

Note also, the bi-directional nature of this equation.

Inserting New Computations

After PPIn_i and PPOut_i are computed, we decide where computations will be inserted:

Insert_i = PPOut_i AND (\neg AvOut_i) AND (\neg PPIn_i OR \neg Transp_i)

This rule states that we really will compute the expression at the end of block i if this is a possible placement point and the expression is not already computed and available and moving the computation still earlier doesn't work because the start of the block isn't a possible placement point or because the block kills the expression.

Removing Existing Computations

We've added computations of the expression to change partial redundancies into full redundancies. Once this is done, expressions that are fully redundant can be removed.

But where?

 $Remove_i = AntLoc_i$ and $PPIn_i$

This rule states that we remove computation of the expression in blocks where it is computed locally and might be moved to the block's beginning.

Partial Redundancy Subsumes Available Expression Analysis

Using partial redundancy analysis, we can find (and remove) ordinary fully redundant available expressions.

Consider a block, b, in which:

(1) The expression is computed (anticipated) locally

and

(2) The expression is available on entrance

Point (1) tells us that AntLoch is true

```
Moreover, recall that
PPIn_b = Const_b AND
  (AntLoch OR ...)
  AND (AvOut<sub>p</sub> OR ... )
    p ∈ Pred(i)
Const_b = AntIn_b AND [PavIn_b OR ...]
We know AntLoc<sub>b</sub> is true \Rightarrow AntIn<sub>b</sub> =
true.
Moreover, AvIn_b = true \Rightarrow PavIn_b = true.
Thus Const_h = true.
If AvIn<sub>b</sub> is true, AvOut<sub>p</sub> is true for all p ∈
Pred(b).
Thus PPIn_h AND AntLoc_h = true =
Remove<sub>h</sub>
```

CS 701 Fall 2006 525

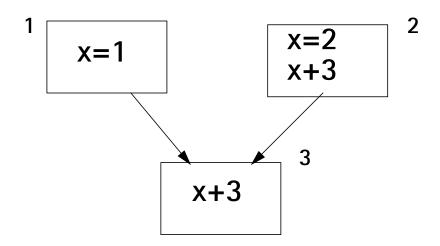

Are any computations added earlier (to any of b's ancestors)?

No:

Insert_i = PPOut_i AND (\neg AvOut_i) AND (\neg PPIn_i OR \neg Transp_i)

But for any ancestor, i, between the computation of the expression and b, AvOut; is true, so Insert; must be false.

Examples of Partial Redundancy Elimination

At block 3, x+3 is partially, but not fully, redundant.

 $PPIn_3 = Const_3 AND$ (AntLoc₃ OR ...)

AND $(PPOut_p \ OR \ AvOut_p)$ $p \in Pred(3)$

Const₃ = Antln₃ AND [PavIn₃ OR ...] Now Antln₃ = true and PavIn₃ = true.

 $Const_3 = true AND true = true$

PPout₁ = PPIn₃ Default initializ

Default initialization of PPIn and PPOut terms is true, since we AND terms together.

 $AntLoc_3 = true.$

 $PPIn_3 = true AND true$

AND $(PPOut_p \ OR \ AvOut_p) = p \in Pred(3)$

 $PPOut_1 AND AvOut_2 = true AND true$ = $PPIn_3 = PPOut_1$.

Insert₁ = PPOut₁ AND (\neg AvOut₁) AND (\neg PPIn₁ OR \neg Transp₁) =

PPOut₁ AND (\neg AvOut₁) AND (\neg Transp₁) = true,

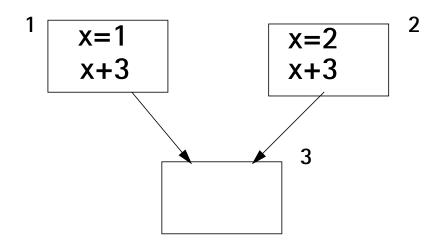

so x+3 is inserted at the end of block 3.

Remove₃ = AntLoc₃ and PPIn₃ = true AND true = true, so x+3 is removed from block 3.

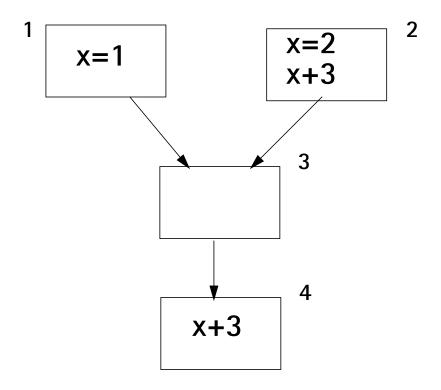

Is x+3 inserted at the end of block 2? (It shouldn't be).

Insert₂ = PPOut₂ AND (
$$\neg$$
 AvOut₂)
AND (\neg PPIn₂ OR \neg Transp₂) =
PPOut₂ AND false AND
(\neg PPIn₂ OR \neg Transp₂) = false.

We now have

Computations May Move Up Several Blocks

Again, at block 4, x+3 is partially, but not fully, redundant.

 $PPIn_4 = Const_4 AND$ (AntLoc₄ OR ...)

AND $(PPOut_p \ OR \ AvOut_p)$ $p \in Pred(4)$

```
Const_4 = AntIn_4 AND [PavIn_4 OR ...]
Now Antln<sub>4</sub> = true and Pavln<sub>4</sub> = true.
Const<sub>4</sub> = true AND true = true
PPout<sub>3</sub> = PPIn<sub>4</sub>.
AntLoc<sub>4</sub> = true.
PPIn_4 = true AND true
   AND (PPOut<sub>p</sub> OR AvOut<sub>p</sub>)
    p \in Pred(4)
PPOut_3 = true.
PPIn_3 = Const_3 AND
  ((Transp<sub>3</sub> AND PPOut<sub>3</sub>) OR ... )
   AND (PPOut<sub>p</sub> OR AvOut<sub>p</sub>)
    p \in Pred(3)
Const_3 = Antln_3 AND [Pavln_3 OR ...]
Antln<sub>3</sub> = true and Pavln<sub>3</sub> = true.
```

CS 701 Fall 2006 531

 $\begin{aligned} & \text{Const}_3 = \text{true AND true} = \text{true} \\ & \text{PPOut}_1 = \text{PPIn}_3 \\ & \text{Transp}_3 = \text{true.} \\ & \text{PPIn}_3 = \text{true AND (true AND true)} \\ & \text{AND (PPOut}_p \text{ OR AvOut}_p) = \\ & p \in \text{Pred(3)} \\ & \text{PPOut}_1 \text{ AND AvOut}_2 = \text{ true AND true} \\ & = \text{PPIn}_3 = \text{PPOut}_1. \end{aligned}$

Where Do We Insert Computations?

```
Insert<sub>3</sub> = PPOut<sub>3</sub> AND (\neg AvOut<sub>3</sub>)

AND (\neg PPIn<sub>3</sub> OR \neg Transp<sub>3</sub>) =

true AND (true) AND

(false OR false) = false

so x+3 is not inserted at the end of

block 3.
```

Insert₂ = PPOut₂ AND (\neg AvOut₂) AND (\neg PPIn₂ OR \neg Transp₂) =

PPOut₂ AND (false)

AND (\neg PPIn₂ OR \neg Transp₂)=false, so x+3 is *not* inserted at the end of block 2.

Insert₁ = PPOut₁ AND (
$$\neg$$
 AvOut₁)
AND (\neg PPIn₁ OR \neg Transp₁) =

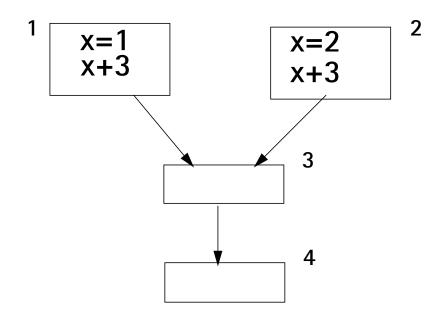

true AND (true) AND $(\neg PPIn_1 OR true) = true$

so x+3 *is* inserted at the end of block 3.

 $Remove_4 = AntLoc_4$ and $PPIn_4$

= true AND true = true, so x+3 is removed from block 4.

We finally have

Code Movement is Never Speculative

Partial redundancy analysis has the attractive property that it never adds a computation to an execution path that doesn't use the computation.

That is, we never *speculatively* add computations.

How do we know this is so?

Assume we are about to insert a computation of an expression at the end of block b, but there is a path from b that doesn't later compute and use the expression.

Say the path goes from b to c (a successor of b), and then eventually to an end node.

Looking at the rules for insertion of an expression:

 $Insert_b = PPOut_b AND ...$

 $PPOut_b = PPIn_c AND ...$

 $PPIn_c = Const_c AND ...$

 $Const_c = AntIn_c AND ...$

But if the expression isn't computed and used on the path through c, then $AntIn_c = False$, forcing $Insert_b = false$, a contradiction.

Can Computations Always be Moved Up?

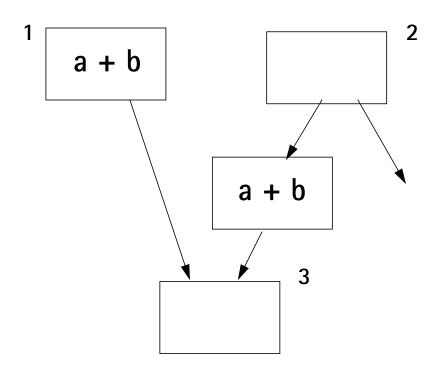

Sometimes an attempt to move a computation earlier in the CFG can be blocked. Consider

We'd like to move a+b into block 2, but this may be impossible if a+b isn't anticipated on all paths out of block 2.

The solution to this difficulty is no notice that we really want a+b computed on the edge from 2 to 3.

If we add an artificial block between blocks 2 and 3, movement of a+b out of block 3 is no longer blocked:

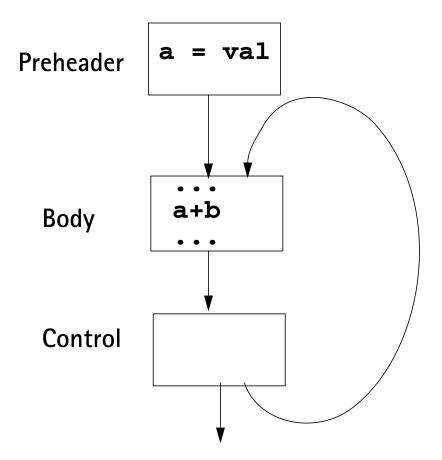

Loop Invariant Code Motion

Partial redundancy elimination subsumes loop invariant code motion. Why?

The iteration of the loop makes the invariant expression partially redundant on a path from the expression to itself.

If we're guaranteed the loop will iterate at least once (do-while or repeat-until loops), then evaluation of the expression can be anticipated in the loop's preheader.

Consider

 $PPIn_B = Const_B AND$ $(AntLoc_B OR ...) AND$ $(PPOut_p AND AvOut_C)$

 $Const_B = AntIn_B AND [PavIn_B OR ...]$

 $AntIn_B = true$, $PavIn_B = true \Rightarrow$

 $Const_B = true$

 $PPout_P = PPIn_B$, $AntLoc_B = true$,

 $AvOut_C = true \Rightarrow PPIn_B = true.$

Insert_P = PPOut_P AND (\neg AvOut_P) AND (\neg PPIn_P OR \neg Transp_P) =

true AND (true) AND $(\neg PPIn_P OR true) = true$, so we may insert a+b at the end of the preheader.

Remove_B = AntLoc_B and PPIn_B = true AND true, so we may remove a+b from the loop body.

What About While & For Loops?

The problem here is that the loop may iterate zero times, so the loop invariant isn't really very busy (anticipated) in the preheader.

We can, however, change a while (or for) into a do while:

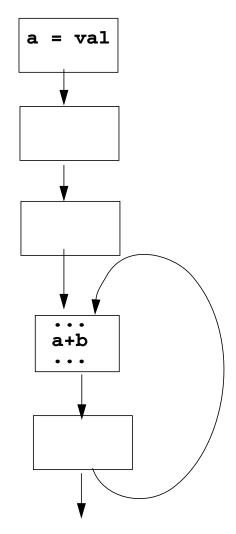

After we know the loop will iterate once, we can evaluate the loop invariant.

Code Placement in Partial Redundancy Elimination

While partial redundancy elimination correctly places code to avoid unnecessary reevaluation of expressions along execution paths, its choice of code placement can sometimes be disappointing.

It always moves an expression back as far as possible, as long as computations aren't added to unwanted execution paths. This may unnecessarily lengthen live ranges, making register allocation more difficult.

For example, in

where will we insert a+b?

Insert_P = PPOut_P AND (\neg AvOut_P) AND (\neg PPIn_P OR \neg Transp_P)

The last term will be true at the top block, but not elsewhere.

In "Lazy Code Motion" (PLDI 1992), Knoop, Ruething and Steffan show how to eliminate partial redundancies while minimizing register pressure.

Their technique seeks to evaluate an expression as "late as possible" while still maintaining computational optimality (no redundant or unnecessary evaluations on *any* execution paths).

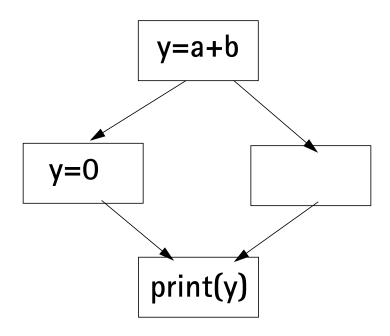

Their technique places loop invariants in the loop preheader rather than in an earlier predecessor block as Morel & Renvoise do.

Partial Dead Code Elimination

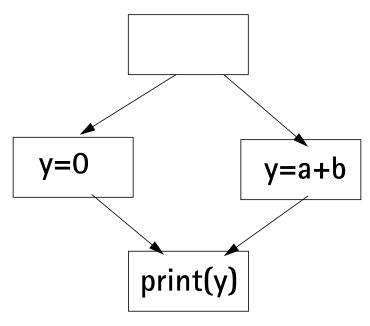

Partial Redundancy Elimination aims to never reevaluate an expression on any path, and never to add an expression on any path where it isn't needed.

These ideas suggest an interesting related optimization—eliminating expressions that are partially dead.

Consider

On the left execution path, a+b is dead, and hence useless. We'd prefer to compute a+b only on paths where it is used, obtaining

This optimization is investigated in "Partial Dead Code Elimination" (PLDI 1994), Knoop, Ruething and Steffan.

This optimization "sinks" computations onto paths where they are needed.
